Nondurable consumption

ABSTRACT

Using the data on maintenance expenditures and self-assessed house value, I separate the measure of individual housing stock and house prices, and use these data for testing whether nondurable consumption and housing are characterized by intratemporal nonseparability in households' preferences. I find evidence in favor of intratemporal dependence between total nondurable consumption and housing. My findings indicate the elasticity of intratemporal substitution between nondurable consumption and housing is higher than the elasticity of intertemporal substitution for composite consumption bundles. Moreover, assuming CES utility, my results are indicative about complementarity between nondurable consumption and housing in the intratemporal preferences.

1. Introduction

Nonseparability in preferences over nondurable consumption and housing is an important feature of many up-to-date consumption models with housing employed in economics and finance. In these models, the intratemporal tradeoff between durable and nondurable consumption and the strength of the intertemporal substitution is key to explaining a variety of important phenomena. [Piazzesi et al. \(2007\)](#) find the strength of the intratemporal elasticity of substitution is an important factor for predictability of excess stock returns, whereas the same modeling feature, to a large extent, allows [Yogo \(2006\)](#) to explain both the cross-sectional variation in expected stock returns and the time variation in the equity premium. [Ogaki and Reinhart \(1998\)](#) argue that accounting for the intratemporal substitution between nondurables and durables improves the estimates of the intertemporal elasticity of substitution. Subsequently, [Flavin and Nakagawa \(2008\)](#) rely on the limited intratemporal substitutability between housing and nondurable consumption in generating a low elasticity of intertemporal substitution to address the observed smoothness of nondurable consumption. [Li et al. \(2016\)](#) demonstrate that the intratemporal elasticity of substitution governs the impact of changes in house prices on household homeownership rates and

nondurable consumption. These studies, however, offer little consensus about the strength of substitutability, ranging from the limited intratemporal substitutability between durable and nondurable consumption (Flavin and Nakagawa, 2008) to a rather flexible one (Piazzesi et al., 2007), which provides different implications about the relative importance between the intratemporal and intertemporal consumption tradeoffs.

In this paper, I test for the intratemporal nonseparability between nondurable consumption and housing in individual preferences. Without making assumptions about the functional form of the utility function, I formulate a consumption model, in which utility depends, probably nonseparably, on two goods: nondurable consumption and housing. Housing stock, from which households-homeowners derive utility, is not constant but is subject to depreciation and upkeep through maintenance and renovations. To investigate empirically the intratemporal dependence over homeowner choices of nondurable consumption and housing, I then exploit *within-household* variation in changes in the housing stock of homeowners who do not change their residence.

Residential housing stock is not constant over the length of the same homeownership and requires significant ongoing maintenance expenses. As measured based on the Panel Study of Income Dynamics (PSID), households spend, on average, around \$2,500 annually on improvement, maintenance, and repair expenditures, which constitutes about 1.6% of house value.¹ With the median maintenance expenditure of only \$600, the average cross-sectional and within-household variation in the maintenance effort is substantial, with the coefficient of variation being 252% and 108%, respectively. To the extent that homeowners expand, remodel, or fail to maintain their homes, fluctuations in both the quality and quantity of their housing stock can be nontrivial.

Although information on homeowners' maintenance effort is observed in various data sources, including the PSID used in this paper, testing whether consumption and housing are nonseparable in household utility is hindered by the inability to accurately observe individual housing stock and its variation over time. Even if a comprehensive set of home attributes is observed, these characteristics usually exhibit little variation or do not change over time. Lack of variation in observed housing characteristics makes it unsuitable for linking to individual variation in consumption. To gain information about variation in housing stock, I use the data on maintenance expenditures and self-assessed house value from the PSID to separate the measure of individual housing stock from house prices of that individual housing stock.² The average housing-stock growth index is somewhat under 1, suggesting that, on average, households' maintenance efforts do not fully offset gross depreciation of housing stock. At the same time, the imputed housing-stock growth varies reasonably over and within households, making it suitable for the analysis of the intratemporal dependence within consumption model. The average index of house-price growth, imputed from the PSID, is also measured with substantial variation. Both nationwide and across regions, it closely matches the level and the pattern of dynamics of the house-price indices, constructed by the U.S. Federal Housing Finance Agency, S&P Case-Shiller, and Zillow. These imputed individual housing-stock and house-price indices are used in estimation of the consumption model.

Exploiting the structure of the consumption Euler equation, this study tests for and finds evidence of intratemporal nonseparability between total nondurable consumption and housing. This finding agrees with the literature that examines and provides evidence against additive separability in preferences over durable and nondurable consumption. Postulating a constant-elasticity-of-substitution (CES) utility function to represent intratemporal preferences over nondurable and durable consumption, intratemporal and intertemporal elasticities of substitution are estimated relying on different sources of variation in durable and nondurable consumption: Ogaki and Reinhart (1998), Pakoš (2011), Piazzesi et al. (2007), and Yogo (2006) exploit time-series variation in aggregated nondurable and durable consumption, Li et al. (2016) rely on cross-sectional variation in the households' house value and income, and Flavin and Nakagawa (2008) use household expenditure on food as a measure of nondurable consumption and discontinuous jumps in housing stock at the time of changing residence, while assuming constant housing stock until the household moves. Unlike these studies, I do not take a stand on the structure of preferences, which makes my findings robust to possible model misspecifications. Similar to Flavin and Nakagawa (2008) and Li et al. (2016), I use household data from the PSID in the test for the intratemporal nonseparability in preferences; however, I focus on the sample of homeowners who do not move and, unlike Flavin and Nakagawa (2008) and Li et al. (2016), rely on both between- and within-household variation in total nondurable consumption and housing stock. Therefore, my results complement and extend the findings of nonseparability between nondurable consumption and housing in those studies to the sample of homeowners who do not move. The economic significance of my findings is supported by the observation that the overwhelming majority of households are homeowners and only a small fraction of them moves at a time.³ My findings are robust to proxying nondurable consumption with food expenditure, and indicate on some heterogeneity over time and householders' age, but not over education groups.

My results suggest the sign of the mixed partial derivative of the utility function is negative, indicating the marginal utility of nondurable consumption declines when housing consumption rises. Under the assumption of power utility combined with the CES intraperiod utility from nondurable and durable consumption, this finding suggests the elasticity of intratem-

¹ Gyourko and Tracy (2006) provide similar evidence from the American Housing Survey on the average annual maintenance and repair expenditures at \$2,051.

² The problem of separating price of housing per unit and the quality-adjusted amount of housing is also recognized and addressed in Combes et al. (2019).

³ Detailed moving statistics for homeowners and renters from the PSID are reported in Bajari et al. (2013). In particular, these authors compute that the average homeowner moves about three times in life.

poral substitution between nondurable and durable consumption is higher than the elasticity of intertemporal substitution for composite consumption bundles. The implication is that intertemporal consumption smoothing is stronger and more important than intratemporal tradeoff between nondurable and durable consumption. Leading to countercyclical marginal utility, this property is central in the study of Yogo (2006) for reconciling the cross-sectional variation in expected stock returns and the time variation in the equity premium. This property, however, is maintained in most consumption models with housing, and in all above-mentioned studies that examine the structure of preferences over durable and nondurable consumption, with the exception of Flavin and Nakagawa (2008). There is much less consensus about the value of the intratemporal elasticity of substitution between nondurable and durable consumption in CES preferences. Although the value less than one is frequent in the surveyed literature (Flavin and Nakagawa, 2008; Li et al., 2016; Pakoš, 2011; Yogo, 2006 and the post-war sample estimate in Piazzesi et al., 2007), using the unit elasticity of intratemporal substitution between nondurable consumption and housing (e.g., Cocco, 2005; Yao and Zhang, 2005) and above (Ogaki and Reinhart, 1998, and the main parameterization in Piazzesi et al., 2007) is not uncommon. My estimation indicates the elasticity of intratemporal substitution is 0.67. Provided the intertemporal elasticity of substitution is usually low, my estimate is fully consistent with my other findings on nonseparability between nondurable consumption and housing, and the relative strength of the intertemporal consumption smoothing over the intratemporal one.

My findings also relate to a large literature that documents an empirical relationship between house-price changes and the households' consumption expenditure (see Aladangady, 2017; Browning, Gørtz and Leth-Petersen, 2013; Campbell and Cocco, 2007; Cooper, 2013; Gan, 2010; Mian, Rao and Sufi, 2013; Paiella and Pistaferri, 2017). An important channel for the relationship between house-price changes and consumption considered in these studies is the housing wealth effect, which suggests house-price appreciation may result in the perception of larger housing wealth and may lead to the increase of consumption expenditure by relaxing households' lifetime resource constraint. Other channels include the collateral borrowing channel, which, under house-price appreciation, relaxes the equity borrowing constraint for households who reached borrowing limits and allows for higher consumption-expenditure levels (DeFusco, 2017), and the channel of common factors that may simultaneously drive house prices and consumption (Attanasio et al., 2009). The intratemporal tradeoff between housing and nondurable consumption can give rise to yet another channel for the relationship between housing wealth and consumption. An increase in construction and maintenance costs may adversely affect the homeowners' demand for maintenance, and, as a result, the quality and quantity of housing stock, the housing wealth of homeowners, and through the intratemporal tradeoff, the consumption expenditure of households who are long in housing.

The remainder of the article is as follows. Section 2 sets up a theoretical model and develops the econometric model. Section 3 describes the data sample and presents a method of measuring unobserved housing stock from the data on maintenance expenditure and house value. Section 4 outlines the estimation strategy and presents the findings. Section 5 provides empirical evidence on the parameter of intratemporal substitution. Section 6 concludes. The further details on derivation of the econometric model and data-sample construction can be found in Online Appendices A-C.

2. Model

Consider households-homeowners who maximize a lifetime utility from consumption and housing:⁴

$$E_t \sum_{s=t}^T \beta^{s-t} U(C_s, H_s) \exp(\rho' z_s), \quad (1)$$

where E_t denotes expectation formed at time t , β is the time discount factor, $U(\cdot)$ is the per-period utility of consumption and housing, and $\exp(\rho' z_t)$ is the taste shifter, which may depend on demographic characteristics z_t . Households derive utility from consumption C_t , and, being homeowners, hold positive amounts of housing stock H_t (priced at P_t), which they manage. The size of the housing stock H_t is interpreted broadly as reflecting not only the physical size, but also its quality. The quantity and quality of housing stock is affected by the depreciation at the rate δ , and by the adjustments to housing stock m_t (also priced at P_t) due to maintenance, renovations, or home improvements:

$$H_t = (1 - \delta)H_{t-1} + m_t. \quad (2)$$

Every period households receive income Y_t , consume C_t , and save B_t (or borrow if negative). If no trade of an existing home occurs, the flow of funds is given by

$$C_t + P_t m_t + B_t = Y_t + R_t B_{t-1}, \quad (3)$$

where R_t is the real interest rate in period t .⁵

⁴ I maintain the assumption of preferences additively separable across time and states of the world. Recently, several studies employ more general Epstein and Zin (1991) preferences that provide the flexibility to disentangle the risk aversion from intertemporal substitution, a feature arguably important to better match the patterns in life-cycle housing decisions, wealth accumulation, and portfolio allocation (Fischer and Khorunzhina, 2019; Pelletier and Tunç, 2019).

⁵ The maintenance expenditure in the budget constraint could also be formulated to depend on housing stock (e.g., a house with a pool might be more expensive to maintain) without further affecting the consumption Euler equation.

Households choose consumption expenditure C_t and housing renovation and upkeep m_t optimally by maximizing (1) subject to (2) and (3). The household's problem implies the following consumption optimality condition:

$$U_C(C_t, H_t) = \beta E_t [R_{t+1} U_C(C_{t+1}, H_{t+1}) \exp(\rho' \Delta z_{t+1})], \tag{4}$$

where U_C is household marginal utility with respect to consumption. Under the assumption of rational expectations, Eq. (4) can be written as follows:

$$\beta R_{t+1} \frac{U_C(C_{t+1}, H_{t+1})}{U_C(C_t, H_t)} \exp(\rho' \Delta z_{t+1}) = 1 + e_{t+1},$$

where e_{t+1} is the expectation error. Assume marginal utilities U_C and U_H are continuously differentiable. Taking logs, and applying first-order Taylor-series expansion to $\ln U_C$, for household i I obtain the estimable Euler equation in log-linearized form:

$$\Delta c_{it+1} = \alpha_0 + \alpha_1 r_{t+1} + \alpha_2 \Delta h_{it+1} + \varrho \Delta z_{it+1} + \epsilon_{it+1}, \tag{5}$$

where r_{t+1} is the log real interest rate in period $t + 1$, $\Delta c_{it+1} = \ln(C_{it+1}/C_{it})$, $\Delta h_{it+1} = \ln(H_{it+1}/H_{it})$, and ϵ_{it+1} is the composite error term that includes the Taylor-series remainder and the expectation error (see Online Appendix A for more details).

Eq. (5) allows us to test for intratemporal nonseparability between nondurable consumption and housing without specifying the structure of preferences for the goods that are separable under the null. Representing $-U_{CH}/U_{CC}$, the coefficient of interest α_2 in equation (5) can be informative about the intratemporal dependence between consumption and housing. Maintaining the standard assumption of $U_{CC} < 0$, the sign of α_2 corresponds to the sign of U_{CH} . Therefore, the coefficient α_2 , statistically insignificantly different from zero, will be the evidence on additive separability between nondurable consumption and housing in contemporaneous utility ($U_{CH} = 0$).

Furthermore, the sign of the mixed partial derivative U_{CH} can be informative about substitutability or complementarity in the sense that nondurable consumption and housing are substitutes (complements) if an increase in housing stock decreases (increases) the marginal utility of nondurable consumption, such that $U_{CH} < 0$ ($U_{CH} > 0$).⁶ In Flavin and Nakagawa (2008), who operate with this definition of complementarity, the sign of the mixed partial derivative of the utility function with respect to the two goods is an important factor determining how the transaction cost associated with trading homes affects the magnitude of the intertemporal elasticity of substitution of nondurable consumption.

Finally, consider the power utility function over a CES intraperiod utility from nondurable consumption and housing, which is the leading model in macroeconomic and finance applications with housing consumption:

$$U(C_t, H_t) = \frac{(C_t^{1-1/\varepsilon} + aH_t^{1-1/\varepsilon})^{1-1/\sigma}}{1 - 1/\sigma}, \quad a > 0, \quad \varepsilon > 0, \quad \sigma > 0, \tag{6}$$

where ε governs the degree of intratemporal substitutability between nondurable consumption and housing, and σ is the intertemporal elasticity of substitution of the composite consumption bundles. The mixed partial derivative of the utility function captures both intratemporal and intertemporal tradeoffs, and the sign of U_{CH} informs about the relative strength of these tradeoffs. The mixed partial derivative of the utility function (6) with respect to the two goods is negative when intertemporal consumption smoothing is more important than intratemporal smoothing ($\varepsilon > \sigma$). That is, households are more willing to substitute housing and nondurable consumption within a period than to substitute composite consumption bundles over different time periods (Piazzesi et al., 2007).

Before estimating Eq. (5), a number of issues need to be taken into consideration. One issue concerns the relevant data. Information on individual housing is usually observed in the form of the monetary value of a house and its physical characteristics. Reported house characteristics (number of rooms, area size in square meters, various housing features, such as patios, balconies, a private garden, etc.) are normally fixed, exhibit little variation over time, and therefore can hardly be used in measuring changes in housing stock. House value in monetary terms is a fusion of many elements, where major factors are the level of local real estate prices and the degree of upkeep implemented by the homeowner to defeat natural wear and tear, and perhaps to even improve the existent quality of housing stock. Eq. (5) requires the measure of housing stock in both its quantity and quality; that is, housing stock must be singled out from the price per unit of housing stock, which equivalently influences the value of a house. I deal with this issue in the next section.

Another issue is related to the possible endogeneity problem in Eq. (5) from the simultaneous choice between a household's consumption and housing and from the Taylor-series approximation used to derive this equation. To deal with this issue, Eq. (5) is estimated using the instrumental variable (IV) technique. The choice of instruments is discussed in Section 4.

3. Data

I construct the data on consumption expenditures, the measure of changes in housing stock, and house-price growth using biennial longitudinal survey observations of households in the US in the Panel Study of Income Dynamics. In particular,

⁶ This definition of complementarity, besides being not invariant to monotone transformations of the utility function (Hicks and Allen, 1934; Kannai, 1980), does not have to agree with other classifications of complementarity (see Samuelson, 1974, for an overview of the different complementarity concepts and interconnections between them).

from the survey on the level of households, I take variables on household consumption, housing wealth, home repairs and maintenance, and demographic characteristics.

3.1. Expenditures

The PSID is a longitudinal survey that follows a nationally representative random sample of families and their extensions since 1968. Since its start, the survey routinely collects information about food expenditures. The set of categories on consumption expenditures expanded significantly in 1999 to include spending on healthcare, education and childcare, transportation, and utilities. With an addition of new spending information on clothing, trips, vacations, entertainment, and the expenditure on home repairs and maintenance in 2005, the PSID currently contains all essential consumption categories. I use data on all these consumption categories, namely, spending on food, clothing, transportation, utilities, trips and vacations, entertainment, healthcare, education, and childcare, and construct total non-housing consumption expenditure as a sum of them. Data on consumption spending are deflated using the consumer price index (CPI) from the CPI releases of the Bureau of Labor Statistics applicable for each spending category (see Online Appendix C).

Housing information includes data on the number of rooms in a dwelling, house value for homeowners, and spending on home repairs and maintenance. The PSID collects information on home repairs and maintenance by asking, “How much did you spend altogether on home repairs and maintenance, including materials plus any costs for hiring a professional?” Homeowners are also asked to provide an assessment of the present value of their house and the lot by giving the value of the home as if it would be sold at the time of survey. Monetary values of housing data are deflated using the CPI index (see Online Appendix C for details). All monetary values are in 2009 dollars.

Motivated by the availability of data on home repairs and maintenance, and a more comprehensive set of consumption categories, from the PSID at the household level, I extract the sample of data on homeownership and housing starting in 2003 and consumption expenditures starting in 2005 and covering biennial observations up to 2015.⁷ Focusing on homeowners, the average homeownership rate in the PSID for this period is remarkably close to the 66.5% reported for these years by the US Census Bureau. The initial sample consists of the continued homeowners ages 22–65 who reside in the US during the time of the interview and do not change residence. I require that a household has non-missing observations over at least three consecutive periods, which imposes a substantial restriction on the initial sample and provides me with 8009 observations on households starting from 2007. Following a common practice in the literature on estimation of consumption models, observations for which total nondurable consumption grows by more than 400% or falls by more than 75% are excluded, which results in further reduction of the sample by 44 observations. Next, observations for which the house reportedly lost more than two thirds of its value or more than doubled its value between consecutive periods, and the increase in house value was not supported by sizable maintenance expenditures, are dropped, which lowers the sample by 121 observations. Observations for which the home was virtually rebuilt, as measured by an unusually high level of maintenance expenditures, are also dropped, which results in omitting 88 observations. Finally, 12 observations for Alaska are not included because housing supply elasticity used in estimation cannot be computed for this state (Chetty et al., 2017).

Altogether, I obtain 7744 observations on homeowners between 2007 and 2015. The consumption Euler equation holds for households who can freely borrow to finance consumption expenditure, and including homeowners who can potentially borrow against their home equity could be adequate to control for liquidity constraints (Runkle, 1991). Following Zeldes (1989) and the recent literature on estimation of consumption models using asset-based sample separation (Alan et al., 2009; Gayle and Khorunzhina, 2018), I also construct a restricted sample by excluding households who do not have a positive balance of financial liquidity (cash, stock, and bond holdings), which results in 6,378 observations for 2007–2015.⁸ Finally, the debt-service ratio (DSR) of Johnson and Li (2010) has been shown to predict the likelihood of being denied credit and is increasingly used as a measure of credit constraints. I construct the ratio between debt-service payments and household income using information on mortgage payments, taxes, insurance payments on primary residences and other real estate, automobile loan and lease payments, and vehicle insurance payments. Following Johnson and Li (2010), I remove households in the top quintile of DSR as constrained, which results in 6,455 observations on households with a low DSR for 2007–2015.

Table 1 presents summary statistics for the data sample. Transportation, food, and health care constitute the three largest consumption-expenditure categories, amounting to about 29%, 22%, and 11% of total consumption expenditures, respectively. Child care, entertainment, and clothing are the three smallest consumption-expenditure categories, amounting to less than 10% of total consumption expenditures, altogether. Expenditure on maintenance is sizable, amounting to 1.58% of house

⁷ Nondurable consumption and maintenance expenditures at the household level are also available in the Consumer Expenditure Survey over a longer period of time, but at the finer, quarterly frequency. After being recorded for four consecutive quarters, households leave the sample and are replaced by new households. Therefore, one cannot construct lower-frequency (annual or biennial) changes in expenditure variables, as in the PSID. Using the PSID is also advantageous for comparing the findings with the related PSID-based studies on the relationship between nondurable consumption and housing, such as Flavin and Nakagawa (2008) and Li et al. (2016).

⁸ Jappelli (1990) selects liquidity-unconstrained individuals, using direct information on borrowing constraints obtained from the Survey of Consumer Finances (SCF). Because the PSID does not provide direct indicators of credit constraints, Jappelli et al. (1998) combine information from the SCF and the PSID to assess the likelihood of a constraint for households in the PSID. A subsequent study of Domeij and Flodèn (2006), however, finds the indicators of liquidity constraints built around the asset-based sample separation rule of Zeldes (1989) and direct information on borrowing constraints in Jappelli (1990) select to a large extent the same households.

value. Financial contributions to improvements and maintenance are routine periodic expenditures for about 79% of households in the sample.

3.2. Housing-stock and house-price growth

Equation of interest (5) requires a measure of changes in a household’s housing stock H_t/H_{t-1} , which, in general, is not observable to an econometrician. Instead, the observables include current and lagged house values ($P_t H_t$ and $P_{t-1} H_{t-1}$) and the maintenance expenditure ($P_t m_t$). Knowing these quantities, using the law of motion for housing stock, given by Eq. (2), and maintaining an assumption that the renovation and maintenance expenditure $P_t m_t$ fully goes into the value of the home, for household i I compute the quantities H_{it}/H_{it-1} and P_{it}/P_{it-1} in the following way:

$$\frac{H_{it}}{H_{it-1}} = \frac{H_{it}}{H_{it} - m_{it}} \cdot (1 - \delta) = \frac{P_{it} H_{it}}{P_{it} H_{it} - P_{it} m_{it}} \cdot (1 - \delta), \tag{7}$$

$$\frac{P_{it}}{P_{it-1}} = \frac{P_{it}}{P_{it-1}} \cdot \frac{H_{it} - m_{it}}{(1 - \delta) H_{it-1}} = \frac{P_{it} H_{it} - P_{it} m_{it}}{P_{it-1} H_{it-1}} \cdot \frac{1}{(1 - \delta)}. \tag{8}$$

In both equations, the second expression substitutes $(1 - \delta) H_{t-1} = H_t - m_t$ from Eq. (2). Whereas computation of P_{it}/P_{it-1} in Eq. (8) relies on longitudinal data on house value, computation of housing-stock growth in Eq. (7) exploits only the cross-sectional dimension of the data on house value and maintenance expenditure. This way of recovering housing-stock growth can be useful in providing a dynamic element to some data sets limited within the cross-sectional dimension. Another important feature of computation of housing-stock growth and house-price growth from Eqs. (7) and (8) is that the depreciation rate enters both equations in a multiplicative way, which limits its effect in estimations that exploit log-transformations of these variables.

Table 1 reports the average values of housing-stock growth and house-price growth, computed from Eqs. (7) and (8), and their standard deviations. For exposition, I set the depreciation rate at 5.0%, which doubles the 2.5% depreciation rate found in Harding et al. (2007) to account for biennial frequency in the data. Also to account for biennial frequency, maintenance expenditures, reported in the survey for a year, are doubled. The average housing-stock growth index is somewhat under 1, suggesting that, on average, households’ maintenance efforts do not fully offset gross depreciation of housing stock. This quality drift of residential housing stock is in agreement with housing literature documenting the depreciation rate *net of maintenance and repair expenditure* between 1% (as in Chinloy, 1979) and 2% (as in Harding et al., 2007) per year. The imputed measure of housing-stock growth also has a sizable standard deviation, which indicates the imputed index varies reasonably over households. The average within-household standard deviation of the housing-stock growth index is 0.03, a

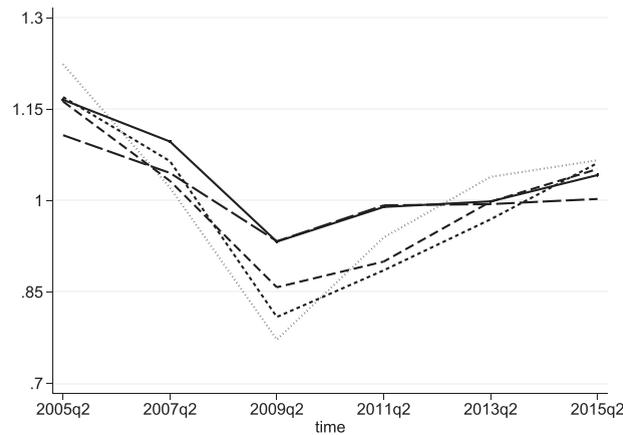

Fig. 1. House-price indices. The solid line shows average house-price growth imputed from the PSID, the long-dashed line shows median house-price growth imputed from the PSID, the dotted line represents S&P Case-Shiller HPI, the dashed line represents FHFA HPI, and the short-dashed line corresponds to the Zillow index.

value of a similar magnitude to the cross-sectional standard deviation, reported in Table 1. The average index of house-price growth is also measured with substantial variation.

The house-price growth index imputed from the PSID is calculated based on the self-reported value of the house, priced by homeowners given the quantity and quality of their housing stock, and therefore may not be directly comparable to the house-price indices (HPIs) used in the literature. Nevertheless, the computed house-price growth from the PSID in Table 1 compares reasonably well to the established HPIs. I compare the imputed house-price growth index from the PSID with the weighted, repeat-sales HPI based on transactions involving single-family homes, constructed by the US Federal Housing Finance Agency (FHFA HPI), and with methodologically similar S&P Case-Shiller HPI. I also use the Zillow Home Value Index (Zillow HVI) for comparison, whose methodology differs from the two aforementioned HPIs, mainly because it does not rely on repeat sales. Instead, it utilizes the Z-estimate, an estimated value of a home based on its proprietary machine-learning algorithm. Zillow's Z-estimate uses multiple sources of data, including prior sales, county records, tax assessments, real estate listings, mortgage information, and geographic information-system data. Importantly, Zillow's website allows homeowners to view the entire history of Z-estimates and to report home improvements, which makes the Zillow HVI index relevant for comparison. The comparative analysis is presented in Fig. 1. This figure reports the average and median house-price growth index imputed from the PSID, S&P Case-Shiller HPI, FHFA HPI, and Zillow HVI for the second quarter of the odd years between 2005 and 2015. During the sample years, the PSID is a biennial survey, in which the overwhelming majority of the interviews are conducted in the second quarter, which explains the choice of the second quarter for comparisons. S&P Case-Shiller HPI, FHFA HPI, and Zillow HVI are adjusted accordingly to show house-price growth for the second quarter of the year relative to the same quarter two years ago. The three well-known HPIs and the one constructed from the PSID paint the same qualitative picture during the observed period. The imputed house-price growth closely matches the level and the pattern of dynamics in house prices over the observed period. The lower volatility of the imputed house-price growth compared to the S&P Case-Shiller HPI, FHFA HPI, and Zillow HVI is consistent with the findings in Davis and Quintin (2017) that, whereby, on average, homeowners tend to report accurate estimates of the current value of their home, during the boom and the bust households update the assessments of their homes gradually, such that self-assessed house prices do not decline as severely as house-price indexes during the bust.

Further analysis shows that similarities between indices' values are even stronger on a regional level. The PSID provides information about a state of residence, which I use in constructing a state and regional measure of the house-price growth index. I compare the imputed house-price growth index from the PSID to HPIs, available on a state level – FHFA HPI and Zillow HVI. Fig. 2 shows the HPIs imputed from the PSID housing data, and the HPI's by the US Federal Housing Finance Agency and Zillow over four major regions: Northeast, North Central, South, and West (see Online Appendix C for the state composition of these regions). State comparisons can be found in Online Appendix C, Figure C1. Overall, the house-price growth index, computed from Eq. (8), is remarkably close to the HPIs reported by Zillow and the US Federal Housing Finance Agency.

4. Estimation and empirical findings

When consumption and re-investment in housing are simultaneous choices, the choice to reinvest in housing stock may be directly affected by the consumption choice and correlated with the unobserved shocks that drive consumption. This possibility creates an endogeneity problem in simultaneous decision-making, and ordinary least-squares estimation of Eq. (5) could result in biased estimates. The remedy is to find instruments, such that they are not affected by nondurable

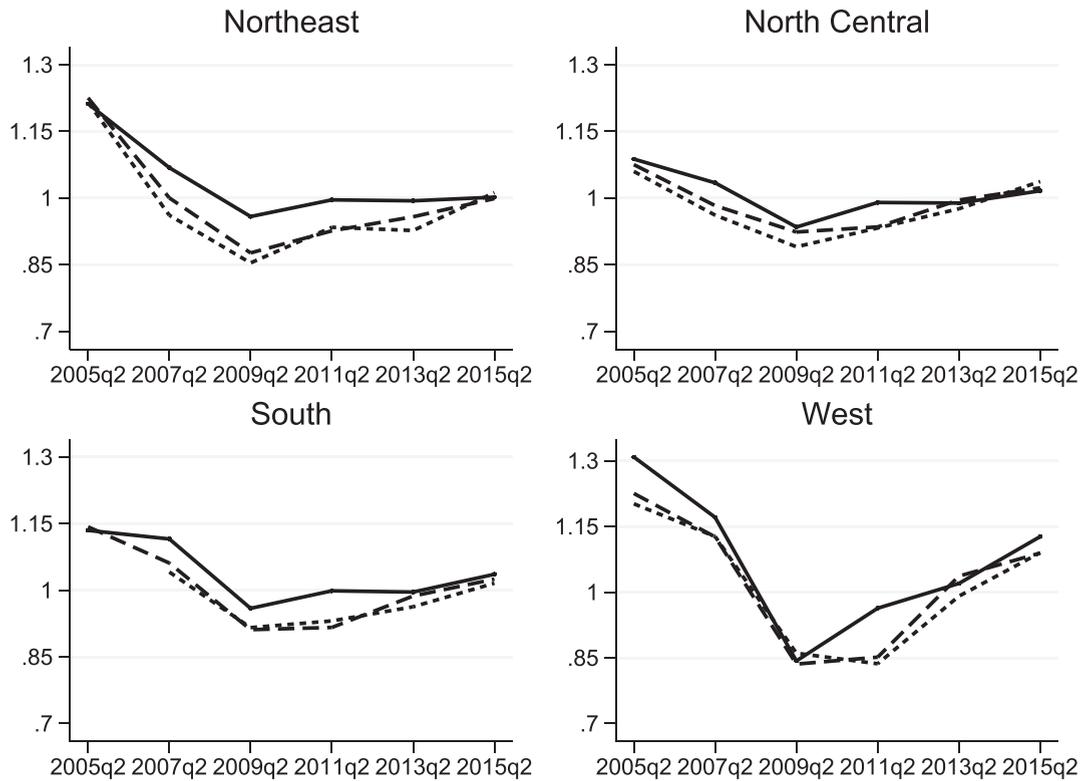

Fig. 2. House-price indices over four regions. The solid line shows average house-price growth imputed from the PSID, the dashed line represents FHFA HPI, and the short-dashed line corresponds to the Zillow index.

consumption but are correlated with changes in housing stock and use an IV estimation technique for obtaining consistent estimates of the parameters in Eq. (5).

As argued in Harding et al. (2007), home attributes tend to be correlated with maintenance and therefore with the changes in housing stock. Indeed, in my data sample, the correlation between house size and level of maintenance expenditures is positive, significantly different from zero at the 1% significance level, and equal to 0.13. Also, home attributes have no natural role in the consumption-model specification (5). Even if home attributes could have affected the consumption level, the observed physical characteristics of the home are usually constant over time and therefore drop out of the model in first differences. Hence, the observed attributes of a home, such as house size, can be used as instruments for reinvestment in Eq. (5).

Household's optimization problem can be supplemented by one more restriction describing the optimal choice of reinvestment in housing stock. The resulting demand for housing stock, along with its dependence on consumption, also depends on house prices (equation (A4) in Online Appendix A). Homeowners manage their housing stock by implementing home improvements, taking prices as given exogenously. House prices have no natural role in the consumption model (see equations (A3)–(A4) in Online Appendix A), and being exogenous to nondurable consumption choice, house prices are relevant for explaining changes in housing stock, making a good instrument. Housing-stock growth and house-price indices (both the imputed individual house-price index and the state-level FHFA HPI) are negatively correlated. For example, the correlation between housing-stock growth and the imputed house-price index in locality is -0.20 and significantly different from zero at the 1% significance level. The negative correlation between housing stock and house prices is in agreement with the restrictions of the demand theory, whereby home improvements are expected to react negatively to the increase in prices.⁹

Lastly, I use the housing supply elasticity measure of Saiz (2010), aggregated to the state level by Chetty et al. (2017), interacted with the real interest rate as an instrument (also used in Aladangady, 2017; Chaney et al., 2012).¹⁰ Since the housing-stock growth is correlated with the local house-price growth, the intuition for using this instrument in the con-

⁹ See empirical estimates of price elasticity of the demand for housing consumption in Rosen (1979), Hanushek and Quigley (1980), Goodman and Kawai (1986), and more recently in Goodman (2002) and Ioannides and Zabel (2003).

¹⁰ State-level housing supply elasticity is available from the replication file for the study of Chetty et al. (2017). I am grateful to the anonymous referee for pointing out this data source.

Table 2
Estimation results.

Δh_{it}	−2.12**	−1.43*	−2.21**
Confidence set	[−4.67, −0.28]	[−2.84, 0.15]	[−4.55, −0.56]
Kleibergen-Paap rk LM statistic	14.34	14.87	14.86
p-value	0.006	0.005	0.005
Hansen J-statistic	3.46	4.58	2.22
p-value	0.33	0.21	0.53
Observations	7,744	6,378	6,455

NOTE: The first-stage results report coefficients; their standard errors are reported in parentheses, clustered by state level, and the Kleibergen-Paap Wald rk F-statistic, adjusted for clustering by state level. Significance levels: 1%***, 5%***, 10%*. The second-stage results report the CUE point coefficient estimates for the housing-stock growth. Weak-instrument-robust confidence sets in square brackets are based on a linear combination (LC) test of 5% K and AR statistics. Instruments include house size, lagged local house-price index computed as in Eq. (8), lagged local house-price index interacted with the lagged state house-price index, and the housing supply elasticity interacted with the real interest rate. All regressions include year dummies, change in a dummy if the husband works, change in a similar dummy for the wife, and demographic controls.

sumption model (5) is similar to the one in Aladangady (2017): changing interest rates affect the user cost of housing and shift housing demand, however its effect can be mitigated or intensified by local geography and land use regulations. This instrument is valid as long as consumption responses to interest-rate shocks do not vary systematically with the housing-supply shifters. Thus, the instruments include house size, the lagged imputed house-price index, which measures house prices specific to the locality of residence, the lagged locality-specific house-price index interacted with the state house-price index, and the housing supply elasticity interacted with the lagged real interest rate.¹¹

To capture the utility taste shifter, in estimation of Eq. (5) I include a set of demographic variables, such as the level of education, change in age squared, and change in family size. Following Mazzocco (2007) and Meghir and Weber (1996), I also include conditioning variables of the change in a dummy if the husband works and the change in a similar dummy for the wife, to capture a possible nonseparability between modelled choices of consumption and housing, and the choice of leisure that is not formally modelled in this paper. Year dummies capture aggregate macroeconomic and financial shifters.

Table 2 reports the estimation results for homeowners (column(1)), homeowners with positive liquidity (column (2)), and homeowners with a low DSR (column (3)). The results from a first-stage regression of housing-stock growth, reported in Table 2, confirm a negative relationship between house prices and housing stock. According to the first-stage results, the estimated coefficients on lagged house-price growth in locality and the same interacted with the lagged house-price index in the state of residence are negative and statistically significant. The coefficients on house size are also negative, suggesting that after controlling for the house-price dynamics, smaller homes experience faster growth in housing stock. Provided that larger homes spend more on repairs and renovation and, per the American Housing Survey of the US Census Bureau, on average, maintain more adequate home quality than smaller homes, their housing stock may not grow as fast.

The F-statistics for the test of the hypothesis that the coefficients on the excluded instruments are zero, reported in Table 2, are between 10.6 and 13.1, which is arguably just outside of the problematic range (Staiger and Stock, 1997; Stock and Yogo, 2005). Nevertheless, the moderate values of the F-statistics can suggest the instruments may potentially be weak. In addition to the robust F-statistics, for each estimation, I report the robust-to-clustering Kleibergen-Paap rk LM test of underidentification and Hansen's J-test of overidentifying restrictions. The main parameter of interest is estimated with the GMM continuously updated estimator (CUE), following the evidence in Hahn et al. (2004) that the CUE estimator is more robust to the presence of weak instruments, and in that case, performs better than the IV or two-step GMM estimators. For all estimations, the Kleibergen-Paap underidentification test rejects the null hypotheses at the 95% level, suggesting the instruments are adequate to identify the equation. Furthermore, Hansen's J-statistic is far from rejection of the null that the overidentifying restrictions are valid, providing me with confidence that the instrument set is appropriate. Finally, for the estimated parameter of interest, I report a weak-instrument-robust confidence set, developed by Andrews (2016). The confidence set is based on a linear combination (LC) test of K-statistic (a score statistic based on the continuously updating GMM objective function as in Kleibergen, 2005) and S-statistic that is a Lagrange multiplier version of the Anderson-Rubin (AR) weak-instruments-robust test (Stock and Wright, 2000).

¹¹ In a similar instrument construction Chetty et al. (2017) and Graham (2018) use housing supply elasticity interacted with house prices (national or regional). For the current study I found this instrument has insufficient power.

NOTE: The table reports the CUE point coefficient estimate for the housing-stock growth, weak-instrument-robust confidence sets in square brackets based on a linear combination (LC) test of 5% K and AR statistics, the Kleibergen-Paap Wald rk F-statistic, adjusted for clustering by state level, the Kleibergen-Paap rk LM test of underidentification, and Hansen's J -test of overidentifying restrictions. Significance levels: 5%**, 10%*. Instruments include house size, lagged local house-price index computed as in Eq. (8), the lagged local house-price index interacted with the lagged state house-price index, and the housing supply elasticity interacted with the real interest rate. All regressions include year dummies, change in a dummy if the husband works, change in a similar dummy for the wife, and demographic controls.

The presentation of the estimation results keeps the focus on the coefficient on housing-stock growth Δh_{it} , which tests whether an intratemporal nonseparability exists between nondurable consumption and housing stock. Estimation results in Table 2 show this coefficient is negative and statistically significant for all samples of homeowners. Overall, the estimation results reject separability in preferences over nondurable consumption and housing. The negative sign of the estimated coefficient provides information about the sign of the mixed partial derivative of the utility function and indicates the marginal utility of nondurable consumption declines when housing consumption rises. In the context of power intertemporal utility combined with the CES intratemporal utility, the negative sign on the mixed partial derivative U_{CH} indicates intertemporal consumption smoothing is more important than intratemporal smoothing ($\varepsilon > \sigma$ in Eq. (6)). This result agrees with empirical findings on the joint estimation of the parameters of intratemporal and intertemporal elasticity of substitution (Li et al., 2016; Ogaki and Reinhart, 1998; Pakoš, 2011; Yogo, 2006). It supports parameterizations of preferences in the life-cycle housing literature (e.g., the influential studies of Cocco, 2005; Yao and Zhang, 2005) and financial literature (Piazzesi et al., 2007).¹²

Because the results for the full sample of homeowners and the restricted subsamples in columns (2)–(3) of Table 2 do not differ substantially, the following set of estimations is conducted on the full sample of homeowners. I test whether an intratemporal dependence exists between separate categories of nondurable consumption and housing stock. This test is possible under the assumption that in the utility, distinct categories of consumption are additively separable but may be pairwise dependent on housing stock. I estimate 10 different models for distinct nondurable consumption categories and report the findings in Table 3. The results indicate the coefficient on housing-stock growth in regressions for most consumption categories is not precisely estimated. Consumption of food, trips and vacations, and utility services (gas, heating fuel, electricity, water and sewer, etc.) are notable exceptions. For these categories of nondurable consumption, the coefficients on housing-stock growth are negative and statistically different from zero at the 5% significance level for food consumption and the 10% one for vacations and utility services, and the magnitude of the estimated coefficients is similar to the ones estimated with total nondurable consumption in Table 2. The finding of nonseparability between housing stock and consumption of utility services is probably not surprising, because home improvements often target a more efficient usage of water and sewer, gas, heating fuel, and electricity. Until the relatively recent expansion of the consumption questionnaire, the PSID survey collected merely the information about food expenditure, which prompted many authors to use it as a proxy for nondurable consumption. Flavin and Nakagawa (2008) estimate a model that nests intratemporal nonseparability between nondurable consumption and housing and a habit-formation component, formulating preferences using the power intertemporal utility and the CES intratemporal utility and using food-consumption data from the PSID. Unlike the findings in the literature cited above, and the results reported in this article, Flavin and Nakagawa (2008) find support for the positive mixed partial derivative of the utility, which, as argued in their study, in the presence of a transaction cost on housing, is needed for the empirically relevant limited responsiveness of nondurable consumption to the interest rate. Distinct to this study, the assumption on constant housing stock for households who do not move is a notable feature of the analysis in Flavin and Nakagawa (2008), which can possibly explain the differences in findings.

¹² Because detecting the relative importance of the intratemporal and intertemporal tradeoffs through the sign of the mixed derivative of the utility does not allow me to capture the individual strengths of the intratemporal or intertemporal substitutions, my findings also agree with the unit elasticity of intratemporal substitution between nondurable consumption and housing (e.g., Cocco, 2005; Davis and Ortalo-Magnè, 2011; Yao and Zhang, 2005) and the limited intratemporal substitution between nondurable consumption and housing (such as the main result in Li et al., 2016, and the post-war sample estimate in Piazzesi et al., 2007, Table C1) as long as the intertemporal elasticity of substitution of the composite consumption bundles over different time periods is low.

Table 4
Estimation results for heterogeneous effects over demographic and cyclical components.

	Heterogeneous effects over:		
	Ae (1)	Education (2)	Cyclical component (3)
Δh_{it}	−3.05** [−4.07, −0.02]	−1.97* [−2.93, 0.92]	−2.96** [−7.24, −1.30]
$\Delta h_{it} \times \text{Old}$	1.21** [0.70, 2.21]		
$\Delta h_{it} \times \text{College}$		0.26 [−0.17, 0.69]	
$\Delta h_{it} \times \text{Bust}$			2.42** [1.91, 3.34]
First-stage robust F-test	5.67	6.78	7.42
Kleibergen-Paap rk LM statistic	14.86	17.61	18.32
p-value	0.038	0.014	0.011
Hansen J-statistic	5.63	5.37	11.63
p-value	0.45	0.50	0.07
Observations	7744	7341	7744

NOTE: The table reports the CUE point coefficient estimate for the housing-stock growth, weak-instrument-robust confidence sets in square brackets based on a linear combination (LC) test of 5% K and AR statistics, the Kleibergen-Paap Wald rk F-statistic, adjusted for clustering by state level, the Kleibergen-Paap rk LM test of underidentification, and Hansen's J -test of overidentifying restrictions. Significance levels: 5%**, 10%*. Instruments include house size, lagged local house-price index computed as in Eq. (8), lagged local house-price index interacted with the lagged state house-price index, and the housing supply elasticity interacted with the real interest rate. The instruments are accordingly interacted with the relevant dummies for age, education, and bust. All regressions include year dummies, change in a dummy if the husband works, change in a similar dummy for the wife, and demographic controls.

Finally, Eq. (5) is estimated, allowing for testing heterogeneous effects in the parameter of interest over age, education, and cyclical component. I divide the sample of homeowners by age groups and interact Δh_{it} with a dummy for households older than 45 (denoted as “Old” in Table 4). Next, I divide the sample between households with only a high school diploma and those with a college degree, and interact Δh_{it} with a dummy for households with a college degree (denoted as “College” in Table 4). Here, I dropped 403 observations for households with less than a high school education. Lastly, to explore the effect of the cyclical component, I construct a dummy variable for the period when house prices declined steeply as opposed to periods of non-declining house prices, and interact Δh_{it} with the bust dummy (denoted as “Bust” in Table 4). The instruments are interacted accordingly with the relevant dummies as well. The results suggest some heterogeneity is present in the estimates. The nonseparability between nondurable consumption and housing is largely present for both young and old households, although it is somewhat weaker for the old households. No decisive heterogeneity is detected over education groups. The results for the cyclical component reveal possible heterogeneity in nonseparability over time, and suggest separability between nondurable consumption and housing may not be rejected during the bust period. This finding, however, is based on only one episode of declining house prices, observed over the sample period, and calls for a further analysis of the factors behind it. It can be affected by the relative strength of the intratemporal and intertemporal consumption-smoothing motives; however, among other factors, it also is affected by the structure of preferences over households' nondurable consumption and housing stock and by the growth rates in those consumption goods, which may also maneuver over business cycles.

5. Estimation of the intratemporal elasticity of substitution

Postulating a CES utility function to represent intratemporal preferences over nondurable and durable consumption, Ogaki and Reinhart (1998), Pakoš (2011), Piazzesi et al. (2007), and Yogo (2006) pin down intratemporal elasticity of substitution using the cointegrating regression of Ogaki and Reinhart (1998). This approach is based on equating marginal rate of substitution between the durable and nondurable consumption goods to the user cost of the service flow for the durable good via the intratemporal first-order condition. Whereas the exact estimation of the intratemporal first-order condition for the CES utility function in microdata framework of this study is challenging because of the variable construction, where housing stock and house prices are measured in growth indices, its approximation is possible. Under perfect foresight on aggregate quantities, the intratemporal first-order condition for the utility function, formulated in Eq. (6), can be represented as $a(H_t/C_t)^{-1/\varepsilon} = P_t \Phi_{t+1}$, where $\Phi_{t+1} = (1 - (P_{t+1}/P_t)(1 - \delta)/R_{t+1})$ (see Online Appendix B for details).¹³ After taking logs

¹³ Iacoviello (2004), Kiyotaki et al. (2011), Poterba (1984), and Skinner (1989) among others allow for a similar treatment of the aggregate quantities in the models with housing.

Table 5
GMM Estimation of Intra-temporal Elasticity.

	(1)	(2)	(3)
ε	0.67 (0.14)	0.78 (0.22)	3.97 (0.29)
J-statistic	8.81	8.89	19.66
p-value	0.55	0.18	0.03

NOTE: Number of households 5,141, a reduced sample by one period due to lags and leads in estimation of Eq. (9). The instrument set for orthogonality conditions includes lagged (that is, $t - 1$) local house-price index interacted with the housing supply elasticity index and the lagged state house-price index, lagged household income growth, lagged growth in hours worked by the husband and wife, and dummy variables for ranges of lagged growth in food consumption expenditure. Standard errors, clustered at the state level, are in parenthesis.

and first differences, this expression for household i can be written as:

$$\Delta c_{it} - \Delta h_{it} = \varepsilon(\Delta p_{it} + \Delta \phi_{it+1}), \tag{9}$$

expressed in terms of the observable consumption growth, housing-stock growth, and local house-price index $\Delta p_{it} = \ln(P_{it}/P_{it-1})$, computed from Eq. (8). The term $\Delta \phi_{it+1} = \ln(\Phi_{it+1}/\Phi_{it})$ depends on the aggregate interest rate and house-price index local to homeowner i and conditional on housing depreciation rate δ . Eq. (9) can be estimated using a minimum distance estimator.

The results are reported in Table 5. Column (1) reports the benchmark estimate of ε , column (2) shows the results after controlling for time fixed effects in Eq. (9), and column (3) shows the results on the specification omitting the term $\Delta \phi_{it+1}$ from Eq. (9). The benchmark estimate of the parameter of intra-temporal substitution implied by the CES utility is 0.67, indicating that housing and nondurable consumption are characterized by limited substitutability. A similar conclusion has been reached in the literature across various levels of data aggregation: for household data in Flavin and Nakagawa (2008) and Li et al. (2016), and for aggregated data in Pakoš (2011) and Yogo (2006). The magnitude of the estimated parameter is close to the values reported in Li et al. (2016), Yogo (2006) and the postwar sample estimate of Piazzesi et al. (2007), whereas Flavin and Nakagawa (2008) and Pakoš (2011) find substantially more limiting substitutability. The standard error by this estimate indicates that the utility function is not likely to be Cobb-Douglas, and ε is not likely to be above one. Whereas the estimate of the intertemporal elasticity of substitution σ for the utility (6) is rather low (as low as 0.02 – 0.04 in Pakoš 2011; Yogo 2006, but up to 0.5 in Ogaki and Reinhart 1998) in studies in which ε and σ are estimated jointly, the value of 0.67 for the intra-temporal substitution is greater than these values for σ . This is fully consistent with the findings in the previous section that intertemporal consumption smoothing is more important than intra-temporal smoothing.

The conclusion about complementarity between nondurable consumption and housing in the intra-temporal preferences holds when controlling for time fixed effects in column (2), although the estimate of ε increases to 0.78, and its standard error is also larger. Once the term $\Delta \phi_{it+1}$ capturing aggregate-quantity effects is dropped from equation (9), the estimate of ε becomes much larger than one, however, this modification results in a model misspecification as detected by the J-test.

6. Conclusion

I test for and find evidence of the intra-temporal nonseparability between total nondurable consumption and housing. My results contribute to the relatively sparse literature investigating the structure of households' preferences over durable and nondurable consumption, and the importance of understanding the preferences over housing and nondurable consumption for academic research and economic policy warrants further research on this topic. For example, my findings are relevant for testing the housing wealth effect on consumption. Because I do not rule out intra-temporal nonseparability between housing and consumption, the tests for other channels between housing prices and consumption expenditure (wealth effect, collateral channel, common factors) for homeowners may likely be hindered by the intra-temporal tradeoff between housing and consumption. The results may also be relevant for the life-cycle literature that often relies on preferences over consumption and housing being additively separable. The evidence on nonseparability in preferences over consumption and housing, found in this paper, suggests that if economic-policy conclusions strongly rely on the assumption of additive separability over consumption and housing in an agent's preferences, then on the disaggregated level, these conclusions may be sensitive to the composition of the target group, in particular in relation to households who are long in housing.
